Eigenfilters: A New Approach to Least-Squares FIR Filter Design and Applications Including Nyquist Filters

P. P. VAIDYANATHAN, MEMBER, IEEE, AND TRUONG Q. NGUYEN, STUDENT MEMBER, IEEE

Abstract—A new method of designing linear-phase FIR filters is proposed by minimizing a quadratic measure of the error in the passband and stopband. The method is based on the computation of an eigenvector of an appropriate real, symmetric, and positive-definite matrix. The proposed design procedure is general enough to incorporate both time- and frequency-domain constraints. For example, Nyquist filters can be easily designed using this approach. The design time for the new method is comparable to that of Remez exchange techniques. The passband and stopband errors in the frequency domain can be made equiripple by an iterative process, which involves feeding back the approximation error at each iteration. Several numerical design examples and comparisons to existing methods are presented, which demonstrate the usefulness of the present approach.

I. INTRODUCTION

IT IS WELL KNOWN that most linear-phase finite impulse response filter (FIR) design problems can be satisfactorily handled by using the McClellan-Parks (MP) algorithm [1] for weighted equiripple filters. These filters have the advantage of providing the designer with the most optimal design in the sense of smallest filter length for a given set of specifications. In contrast, a number of authors have also considered the *least-squares* approach for FIR filter design [2]–[6]. As outlined in [5], [6], and [31], there are some advantages under certain situations where these methods have to be preferred over the Remez exchange techniques.¹ Most least-squares techniques advanced so far are based on solving a set of linear simultaneous equations by matrix inversion.

Consider a typical low-pass design problem: we wish to approximate a “desired response” $D(\omega)$ with a type-1 linear-phase FIR filter transfer function $H(z)$

$$H(z) = \sum_{n=0}^{N-1} h_n z^{-n}. \quad (1)$$

(A type-1 filter has $h_n = h_{N-1-n}$ and, moreover, the order

¹“Remez exchange algorithm” and the “MP approach” are used synonymously in this paper.

$N-1$ is even [7].) The desired response is

$$D(\omega) = \begin{cases} 1, & 0 \leq \omega \leq \omega_p \\ 0, & \omega_S \leq \omega \leq \pi \\ \text{don't care,} & \omega_p < \omega < \omega_S \end{cases} \quad (2)$$

whereas the amplitude response of $H(z)$ is [7]

$$H_0(e^{j\omega}) = \sum_{n=0}^{N-1} h_n e^{-j(n-M)\omega} = \sum_{n=0}^M b_n \cos n\omega \quad (3)$$

where $M = (N-1)/2$ and

$$b_n = \begin{cases} 2h_{(N-1)/2-n}, & n \neq 0 \\ h_{(N-1)/2}, & n = 0 \end{cases} \quad (4)$$

The least-squares (LS) approach [2] to this problem is to formulate an objective function

$$E_{LS} = \int_R [D(\omega) - H_0(e^{j\omega})]^2 \frac{d\omega}{\pi} \quad (5)$$

where R is the region $0 \leq \omega \leq \pi$, but excluding the transition band. The parameters b_n are found by minimizing E_{LS} . The actual computation of b_n can be performed [2] by solving simultaneously a set of linear equations (or by matrix inversion)

$$\mathbf{b} = \mathbf{A}^{-1} \mathbf{c} \quad (6)$$

where $\mathbf{b} = (b_0 b_1 \cdots b_M)'$; \mathbf{c} and \mathbf{A} are quantities depending upon ω_p and ω_S . By incorporating a weighting function into the integrand of (5), one can attain a tradeoff between passband and stopband accuracies.

Several interesting design examples can be found in [2]. Fig. 1 shows a typical magnitude response $|H_0(e^{j\omega})|$ of such a least-squares FIR filter. A particular special case of the above approach gives rise to the prolate-spheroidal wave sequence as the solution [2]. This corresponds to minimizing

$$E_{LS} = \int_{\omega_S}^{\pi} [D(\omega) - H_0(e^{j\omega})]^2 \frac{d\omega}{\pi} \quad (7)$$

under a suitable constraint (such as $\sum h_n^2 = 1$). The resulting amplitude response is typically shown in Fig. 2. The prolate-spheroidal solution vector $\mathbf{h} = [h_0, h_1, \dots, h_{N-1}]'$ (and, hence, \mathbf{b}) can be found as the eigenvector of a real, symmetric, and positive-definite matrix [2] (which happens

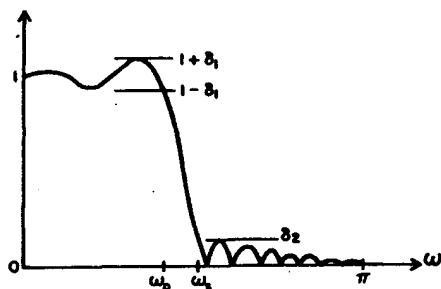

Fig. 1. Typical magnitude response of a least-squares FIR filter.

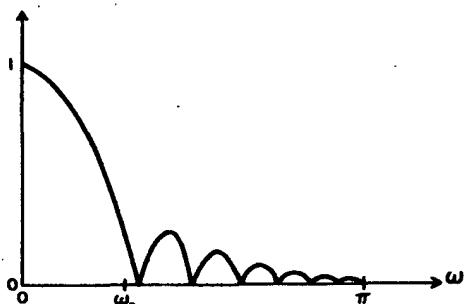

Fig. 2. Typical magnitude response of a Kaiser window.

to be Toeplitz). For reasonably large N , this solution \mathbf{h} can be approximated to a very high degree of accuracy by closed-form expressions based on the zeroth-order Bessel function $I_0(x)$. Such closed-form expressions have been introduced and used by Kaiser [18] for the design of the "Kaiser window." Since the Kaiser window is a closed-form approximation for the above eigenvectors, the latter need not be computed by elaborate eigensystem subroutines.

Notice that the least-squares filter response shown in Fig. 2 is itself not a "good" low-pass response; in order to obtain an acceptable low-pass response (based on the LS approach), the passband region $0 < \omega < \omega_p$ must be included in the objective function E_{LS} of (5). Fig. 2 represents a specific instance of the LS problem where the solution vector is an eigenvector of an appropriate real, symmetric, and positive-definite matrix. On the other hand, Fig. 1 represents another instance of the LS problem where the solution corresponds to an acceptably good low-pass response, but cannot be obtained as the eigenvector of an appropriate matrix. The question that arises in this context is, can we formulate an appropriate objective function E such that the filter coefficients can be obtained from an eigenvector of an appropriate matrix, and at the same time give rise to a low-pass response as in Fig. 1? In other words, can we obtain a linear-algebraic generalization of the prolate-sequences (or the Kaiser window) so that the resulting vector itself has a response as in Fig. 1?

The purpose of this paper is to address this question. The answer turns out to be in the affirmative, and we discuss the solution and several applications of this result. Such FIR filters whose coefficients are the components of eigenvectors will be termed "eigenfilters." The idea of using an eigenvector in order to find the coefficients of a FIR filter has been used earlier in other contexts [16]. The

well-known technique of Pisarenko [17] for harmonic retrieval is such an example. Even though eigenvectors have been used in the past for filtering applications (for example, see [6]), we believe that the present formulation is novel in the sense that it takes care of the passband accuracy directly. Section II formulates the new quadratic objective function and includes design examples of such low-pass filters. In Section III, we show how certain time-domain constraints can be taken into account along with the usual frequency-domain specifications while designing these eigenfilters. Section IV presents a method for designing eigenfilters which have equiripple behavior both in the passband and stopband; the method is based on iteratively feeding back the approximation error into the integrand of (5) by incorporating a weighting function. The obvious question that comes to mind in this context is, why should we use a quadratic measure at all, rather than an L_∞ measure, if we are interested only in an equiripple result? The justification is that we can now include time-domain constraints if we use the eigenfilter approach, and at the same time obtain a more or less equiripple frequency response. In Section V, we show how eigenfilters can be used for the design of M th-band filters (and Nyquist filters). The results are compared with other recently reported techniques [8], [9] for the design of Nyquist filters. Section VI describes how one can employ the eigenfilter approach to design filters which have flatness constraints (or tangency constraints) at any given frequency in the passband. In the last section, we make comments on the computational aspects involved in finding the appropriate eigenvector.

II. LINEAR PHASE FIR Low-Pass EIGENFILTERS

Let $H(z)$ be an FIR transfer function as in (1). We wish to obtain a low-pass frequency response as in Fig. 1, by minimizing an error measure of the form

$$E = \mathbf{v}' \mathbf{P} \mathbf{v} \quad (8)$$

where \mathbf{P}^2 is a real, symmetric, and positive-definite matrix depending upon the design requirement, and \mathbf{v} is a real vector related to \mathbf{h}_n in some simple manner (to be elaborated). We assume an implicit constraint $\mathbf{v}' \mathbf{v} = 1$ to avoid trivial solutions. We wish the error measure E to reflect both the passband deviation and the stopband deviation from the ideal values of (2). Once such a measure is formed, the solution vector \mathbf{v} is simply the eigenvector of \mathbf{P} corresponding to its minimum eigenvalue in view of the well-known Rayleigh's principle [19]. We impose the additional condition that the resulting transfer function $H(z)$ should have linear phase, i.e.,

$$\mathbf{h}_n = \mathbf{h}_{N-1-n} \quad (9)$$

where the order $N-1$ could be either even (type 1) or odd (type 2) [7]. We do not consider antisymmetric impulse

²Notations used in the paper: Bold-faced letters indicate vectors and matrices. Superscript t stands for transposition, whereas superscript dagger (\dagger) stands for transposition followed by complex conjugation. Real symmetric positive-definite matrices \mathbf{P} are indicated by the notation $\mathbf{P} = \mathbf{P}^t > 0$, and satisfy the property $\mathbf{y}' \mathbf{P} \mathbf{y} > 0$ for all $\mathbf{y} \neq 0$.

response sequences in this section because they cannot be used in low-pass designs [7].

With $H(z)$ satisfying (9), its frequency response takes the form

$$H(e^{j\omega}) = e^{-j(N-1)/2\omega} H_0(e^{j\omega}) \quad (10)$$

where $H_0(e^{j\omega})$ is real-valued, given by [7]

$$H_0(e^{j\omega}) = \begin{cases} \sum_{n=0}^M b_n \cos n\omega, & N-1 \text{ even} \\ \sum_{n=0}^{M-1} b_n \cos \left(n + \frac{1}{2}\right)\omega, & N-1 \text{ odd} \end{cases} \quad (11)$$

The quantity M in (11) is defined as $M = (N-1)/2$ for even $N-1$, and $M = N/2$ for odd $N-1$. Defining

$$\mathbf{b} = \begin{cases} [b_0 \ b_1 \cdots b_{M-1} \ b_M]', & N-1 \text{ even} \\ [b_0 \ b_1 \cdots b_{M-2} \ b_{M-1}]', & N-1 \text{ odd} \end{cases} \quad (12a)$$

and

$$\mathbf{c}(\omega) = \begin{cases} [1 \ \cos \omega \ \cos 2\omega \cdots \cos M\omega]', & N-1 \text{ even} \\ \left[\cos \frac{\omega}{2} \ \cos \frac{3\omega}{2} \cdots \cos \left(M - \frac{1}{2}\right)\omega\right]', & N-1 \text{ odd} \end{cases} \quad (12b)$$

we can write (11) as

$$H_0(e^{j\omega}) = \mathbf{b}' \mathbf{c}(\omega). \quad (13)$$

For notational simplicity, $\mathbf{c}(\omega)$ will often be denoted as \mathbf{c} . For even $N-1$, the quantities b_n are as in (4). For odd $N-1$, $b_n = 2h_{M-1-n}$.

With the "desired response" as in (2), the "stopband error" can now be defined as

$$E_S = \frac{1}{\pi} \int_{\omega_S}^{\pi} [D(\omega) - H_0(e^{j\omega})]^2 d\omega = \frac{1}{\pi} \int_{\omega_S}^{\pi} \mathbf{b}' \mathbf{c} \mathbf{c}' \mathbf{b} d\omega = \mathbf{b}' \mathbf{P}_S \mathbf{b} \quad (14)$$

where \mathbf{P}_S is given by

$$\mathbf{P}_S = \frac{1}{\pi} \int_{\omega_S}^{\pi} \mathbf{c} \mathbf{c}' d\omega \quad (15)$$

and is a real, symmetric, and positive definite matrix (unless $\omega_S = \pi$, which is a case of no interest).

If the passband error measure E_p is also defined according to the integral of (5), the total error measure cannot be written in the form (8). Accordingly, let us define E_p differently. First, notice that the zero-frequency response is given by

$$H_0(e^{j0}) = \mathbf{1}' \mathbf{b} \quad (16)$$

where the vector $\mathbf{1}$ is defined as

$$\mathbf{1} = [1 \ 1 \cdots 1]'. \quad (17)$$

The quantity $e_p(\omega) = (\mathbf{1} - \mathbf{c})' \mathbf{b}$, therefore, represents the deviation of the response $H_0(e^{j\omega})$ from the zero-frequency response.³ Accordingly, a positive-valued (quadratic) error

measure for the passband can be taken as

$$E_p = \frac{1}{\pi} \int_0^{\omega_p} e_p^2(\omega) d\omega = \frac{1}{\pi} \int_0^{\omega_p} \mathbf{b}' (\mathbf{1} - \mathbf{c}) (\mathbf{1} - \mathbf{c})' \mathbf{b} d\omega \quad (18)$$

which can be written in the form

$$\mathbf{E}_p = \mathbf{b}' \mathbf{P}_p \mathbf{b} \quad (19)$$

where \mathbf{P}_p is given by

$$\mathbf{P}_p = \frac{1}{\pi} \int_0^{\omega_p} (\mathbf{1} - \mathbf{c}) (\mathbf{1} - \mathbf{c})' d\omega \quad (20)$$

and is a real, symmetric, positive-definite matrix (unless $\omega_p = 0$). Thus, the total measure to be minimized is

$$\mathbf{E} = \mathbf{b}' \mathbf{P} \mathbf{b} \quad (21)$$

where

$$\mathbf{P} = (1 - \alpha) \mathbf{P}_p + \alpha \mathbf{P}_S. \quad (22)$$

The quantity α , which is in the range $0 \leq \alpha \leq 1$, controls

the relative accuracies of approximation in the pass and stopbands. Notice that the elements of \mathbf{P} are given by

$$\mathbf{P}(n, m) = \frac{(1 - \alpha)}{\pi} \int_0^{\omega_p} (1 - \cos n\omega) (1 - \cos m\omega) d\omega + \frac{\alpha}{\pi} \int_{\omega_S}^{\pi} (\cos n\omega \cos m\omega) d\omega, \quad N \text{ odd} \quad (23a)$$

$$\mathbf{P}(n, m) = \frac{(1 - \alpha)}{\pi} \int_0^{\omega_p} \left(1 - \cos \left(n + \frac{1}{2}\right)\omega\right) \left(1 - \cos \left(m + \frac{1}{2}\right)\omega\right) d\omega + \frac{\alpha}{\pi} \int_{\omega_S}^{\pi} \left[\cos \left(n + \frac{1}{2}\right)\omega\right] \left[\cos \left(m + \frac{1}{2}\right)\omega\right] d\omega, \quad N \text{ even.} \quad (23b)$$

In summary, we have been able to formulate the linear-phase low-pass FIR design problem in the form of an eigenproblem. Given the band edges ω_p and ω_S , and the parameter α , the matrix \mathbf{P} can be computed. It is easy to obtain closed-form expressions for the integrals in (23), and, hence, the elements $\mathbf{P}(n, m)$ are easily computed once α , ω_p and ω_S are known. It then remains only to compute the eigenvector of a real, symmetric, and positive-definite matrix corresponding to the smallest eigenvalue. The resulting filter is guaranteed to have linear phase because the vector \mathbf{b} rather than the vector \mathbf{h} is directly involved in the optimization problem. The eigenvector \mathbf{b} can be used to obtain the filter coefficients h_n in (1). We now proceed with design examples to demonstrate the procedures.

³The only motivation for taking zero-frequency as a reference for passband error formulation is that it brings the vector \mathbf{b} into the reference, and this enables us to write E_p as a quadratic in \mathbf{b} . This in turn leads to the eigenformulation.

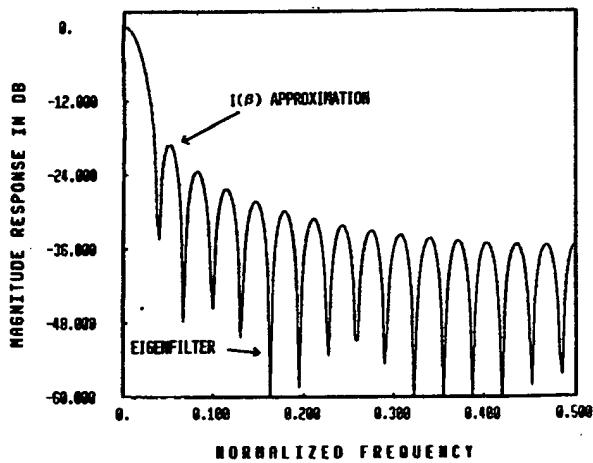

Fig. 3. (Ex. 1) Magnitude response plot of Kaiser window using eigenfilter and $I(\beta)$ approximation.

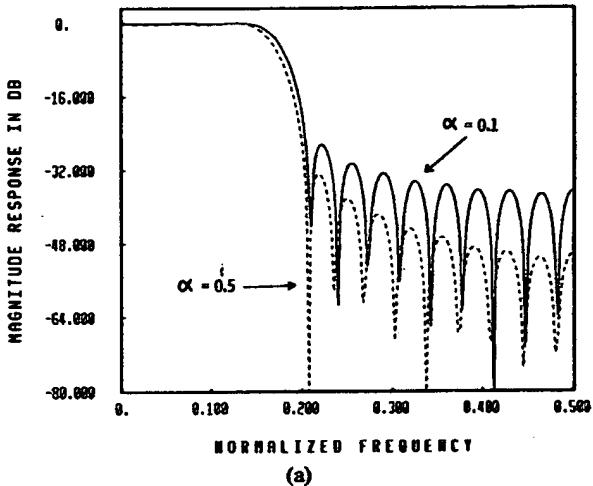

Fig. 4. (Ex. 2) (a) Magnitude response plot of FIR eigenfilter. (b) Passband details for the FIR eigenfilter.

Example 1: Let $\omega_s = 0.05\pi$ and let $\alpha = 1$ in (22). Then ω_p does not enter into the optimization problem. With $N - 1 = 30$, the eigenvector \mathbf{b} corresponding to the minimum eigenvalue of \mathbf{P} was computed. The resulting frequency response $H_0(e^{j\omega})$ is shown in Fig. 3 in solid lines. The broken line represents the transform of the

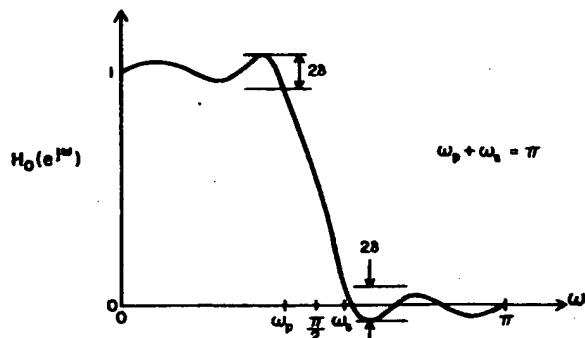

Fig. 5. Typical amplitude response of a half-band FIR filter.

Kaiser window for a window length of 31, and an appropriate value of the window parameter [7] given by $\beta = 2.0$. This example is only a demonstration that the Kaiser window is an excellent closed-form approximation for certain eigenfilters (the prolate spheroidal sequences).

Example 2: A low-pass filter with $N - 1 = 28$, $\omega_p = 0.3\pi$, $\omega_s = 0.4\pi$, and $\alpha = 0.1$ was designed using the above approach. The resulting frequency response is shown in Fig. 4, which also includes the plot for the case of $\alpha = 0.5$. The effect of α is clearly seen from the figure.

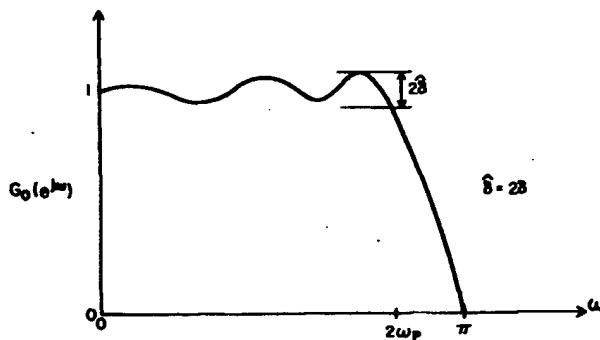

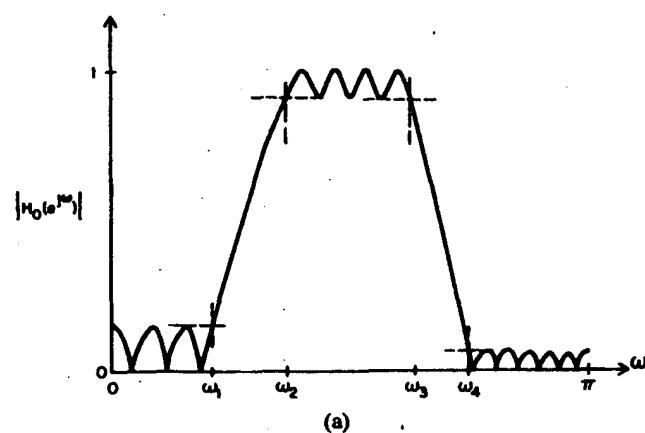

Comments on the Choice of α : It is clear from (22) that a larger value of α leads to better stopband attenuation at the cost of increased passband ripple. Given the set of specifications ω_p , ω_s , passband tolerance δ_1 and stopband tolerance δ_2 , it is necessary to estimate $N - 1$ and α in order to design the eigenfilter. An approximate estimate for $N - 1$ can be obtained based on the relations in [20]. Even though the estimates in [20] hold only for equiripple designs, the required order for an eigenfilter is only slightly larger. The choice of α governs the ratio δ_1/δ_2 . At this time, we do not have a procedure for estimating α , starting from a desired δ_1/δ_2 ratio. Further study of the behavior of eigenfilters is necessary in order to fill this gap.

The following example demonstrates the design of a half-band filter [8], [11] based on the eigenfilter approach. For this example, the quantity α does not come into the picture at all, in view of the indirect procedure described below.

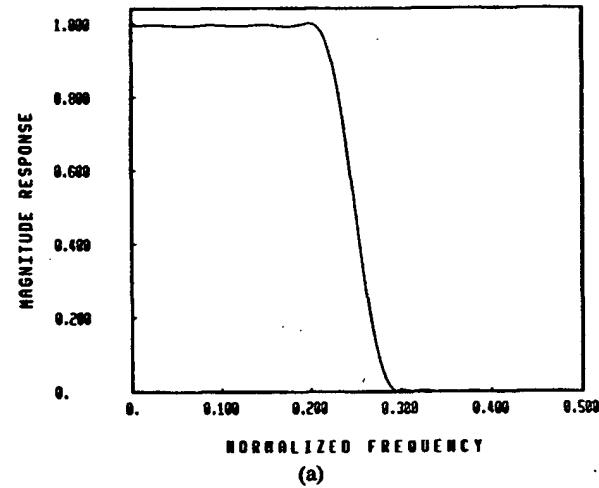

Example 3: A linear-phase FIR half-band filter is a type-1 low-pass filter having an amplitude response $H_0(e^{j\omega})$ that is symmetric with respect to $\pi/2$ as shown in Fig. 5. Note that $\omega_p + \omega_s = \pi$, and $\delta_1 = \delta_2$ for such filters. It can be shown that for such filters h_n satisfies

$$h_n = 0 \quad \text{for } n - \frac{N-1}{2} = \text{even} \neq 0. \quad (24)$$

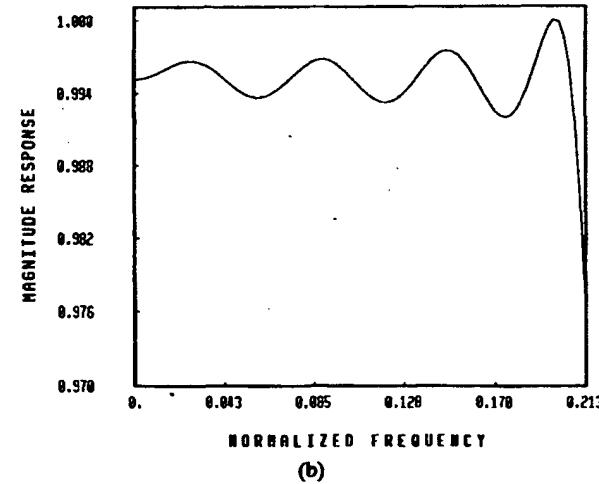

A direct design of such filters based on any design methodology (such as the McClellan-Parks program, or eigenfilter methods) invariably leads to a filter which does not satisfy (24) exactly, due to the computational inaccuracies. In addition, since about half of the impulse response coefficients are known anyway, it is only judicious to eliminate the known variables from the design problem so as to reduce computational time. This can be accomplished by designing $H(z)$ by a two-stage process. The first step is

Fig. 6. Amplitude response of $G(z)$.

(a)

(a)

(b)

Fig. 7. (Ex. 3) (a) Response of the half-band eigenfilter. (b) Passband details for the half-band eigenfilter.

the design of a one-band linear phase filter $G(z)$ of odd order $(N-1)/2$ with response as in Fig. 6, where $\delta = 2\delta$.

The passband of $G(z)$ is the interval $0 < \omega < 2\omega_p$, and the region $2\omega_p < \omega < \pi$ is the transition band. Since $(N-1)/2$ is odd, $G(e^{j\omega})$ is automatically zero at $\omega = \pi$ [7]. Now, $H(z)$, which has a desired response as in Fig. 5, can be obtained as

$$H(z) = \frac{G(z^2) + z^{-(N-1)/2}}{2}. \quad (25)$$

Given the specifications ω_p and δ for the half-band filter,

Fig. 8. (Ex. 4) (a) Typical magnitude response of a bandpass FIR filter. (b) Magnitude response plot of a bandpass FIR eigenfilter.

the specifications $2\omega_p$ and δ in Fig. 6 are known. The order of $G(z)$ is half the order of $H(z)$ and $G(z)$ can be designed much more quickly. Moreover, the computation of $H(z)$ as in (25) ensures that (24) is satisfied exactly, with no error. More details in this connection can be found in [32].

The eigenfilter approach can be used easily to design the odd-order one-band filter $G(z)$ with response as in Fig. 6, simply by taking $\alpha = 0$ in (22) and letting

$$P = P_p = \frac{1}{\pi} \int_0^{2\omega_p} (1-c)(1-c)^t d\omega. \quad (26)$$

The eigenvector b contains information about the impulse response g_n of $G(z)$. The impulse response of $H(z)$ is found as

$$h_n = \begin{cases} 0.5g_{n/2}, & n \text{ even} \\ 0, & n \text{ odd } \neq \frac{N-1}{2} \\ \frac{1}{2}, & n = \frac{N-1}{2} \end{cases}. \quad (27)$$

Fig. 7 shows the frequency response of a half-band filter designed using the above eigenfilter approach. Here, $N-1 = 34$ and $\omega_p = 0.4225\pi$.

Example 4: The design of high-pass and bandpass eigenfilters can be accomplished with equal ease. For example, a type-1 bandpass filter can be designed by defining the objective function E as $E = \alpha E_1 + \beta E_2 + (1 - \alpha - \beta) E_3$, where $\alpha, \beta > 0$ and $1 - \alpha - \beta > 0$. E_1 and E_2 represent the stopband errors

$$E_1 = \frac{1}{\pi} b' \int_0^{\omega_1} cc' d\omega b \quad E_2 = \frac{1}{\pi} b' \int_{\omega_2}^{\omega_3} cc' d\omega b$$

and E_3 is the quadratic measure of passband error defined as

$$E_3 = \frac{1}{\pi} b' \int_{\omega_2}^{\omega_3} (a - c)(a - c)' d\omega b.$$

Here, a is a constant vector of the form

$$a = [1 \quad \cos \omega_0 \quad \cos 2\omega_0 \cdots]$$

and ω_1 , ω_2 , ω_3 , and ω_4 are the band edges as shown in Fig. 8(a). The quantity ω_0 is taken as $\omega_0 = (\omega_2 + \omega_3)/2$. Fig. 8(b) shows the response for a design example where the order is $N-1 = 50$, and the band edges are $\omega_1 = 0.3\pi$, $\omega_2 = 0.35\pi$, $\omega_3 = 0.7\pi$, and $\omega_4 = 0.8\pi$.

III. EIGENFILTERS WITH SIMULTANEOUS TIME-DOMAIN CONSTRAINTS

Error functions that are more general than (21) can be formulated in order to take into account time-domain constraints. As an example, let us assume that we wish to design a linear-phase low-pass FIR filter as in Fig. 9. Let us assume that, in the input signal $x(n)$, there are occasional segments of an unwanted waveform, i.e., a finite duration waveform of the type

$$s_0, s_1, \dots, s_{L-1}. \quad (28)$$

The time of occurrence of this L -point waveform is unknown, but its shape is known. We would like $H(z)$ in (1) to be such that, in addition to being a good low-pass filter, it minimizes the effect of s_k on the output signal y_n . Thus, let

$$r_n = \sum_{k=0}^{N-1} h_k s_{n-k}, \quad n = 0, 1, \dots, L+N-2 \quad (29)$$

represent the $(L+N-1)$ -point sequence at the output in response to the L -point input in (28). In matrix form, we have

$$r = Sh$$

where

$$S = \begin{pmatrix} s_0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ s_1 & s_0 & 0 & \cdots & 0 & 0 & 0 \\ s_2 & s_1 & s_0 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ s_{L-1} & s_{L-2} & s_{L-3} & \cdots & s_0 & 0 & 0 \\ 0 & s_{L-1} & s_{L-2} & \cdots & s_1 & s_0 & 0 \\ 0 & 0 & s_{L-1} & \cdots & s_2 & s_1 & s_0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & s_{L-1} & s_{L-2} & s_{L-3} \\ 0 & 0 & 0 & \cdots & 0 & s_{L-1} & s_{L-2} \\ 0 & 0 & 0 & \cdots & 0 & 0 & s_{L-1} \end{pmatrix} \quad (30)$$

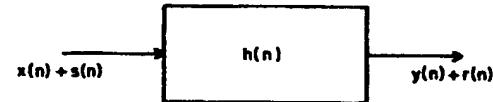

Fig. 9. System with input noise.

$$r = [r_0 \quad r_1 \cdots r_{N+L-2}]' \quad (31)$$

$$h = [h_0 \quad h_1 \cdots h_{N-1}]'. \quad (32)$$

A quadratic measure of the output error is given by $r'r$. Define a normalized measure of output "noise" by

$$E_N = \frac{h'S'Sh}{s's} \quad (33)$$

where

$$s = (s_0 \quad s_1 \cdots s_{L-1})'. \quad (34)$$

In order to preserve the linearity of the phase of $H(z)$, it is necessary to write E_N in terms of the b vector so that the b vector can be made the "unknown" vector of the optimization problem. For this, notice that the vectors h (eq. (32)) and b (eq. (12a)) are related as $h = Db$, where

$$D = \frac{1}{2} \begin{pmatrix} 0 & 0 & 0 & \cdots & \cdots & 1 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 1 & \cdots & \cdots & 0 \\ 0 & 1 & 0 & \cdots & \cdots & 0 \\ 2 & 0 & 0 & \cdots & \cdots & 0 \\ 0 & 1 & 0 & \cdots & \cdots & 0 \\ 0 & 0 & 1 & \cdots & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & \cdots & 1 \end{pmatrix} \quad \text{for } N-1 \text{ even (35)}$$

and

$$D = \frac{1}{2} \begin{pmatrix} 0 & 0 & 0 & \cdots & 0 & 1 \\ 0 & 0 & 0 & \cdots & 1 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 1 & 0 & \cdots & 0 & 0 \\ 1 & 0 & 0 & \cdots & 0 & 0 \\ 1 & 0 & 0 & \cdots & 0 & 0 \\ 0 & 1 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & 0 \\ 0 & 0 & 0 & \cdots & 0 & 1 \end{pmatrix} \quad \text{for } N-1 \text{ odd. (36)}$$

Thus, E_N simplifies to

$$E_N = b' P_N b \quad (37)$$

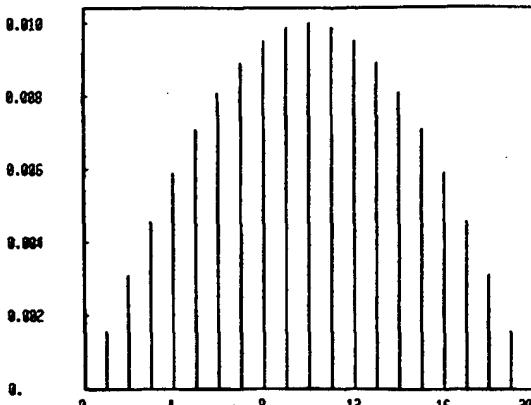

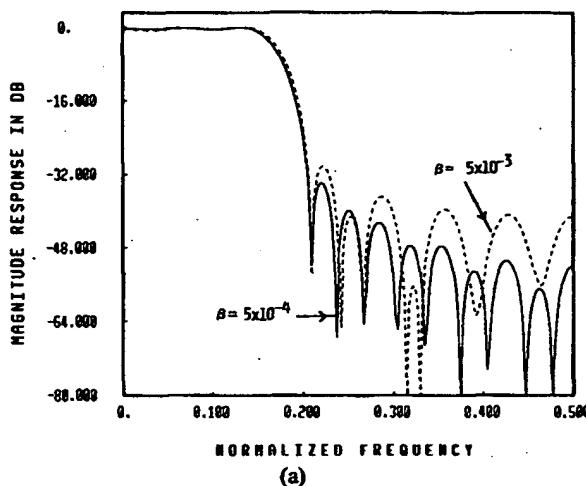

where

$$P_N = \frac{D'S'SD}{s's}. \quad (38)$$

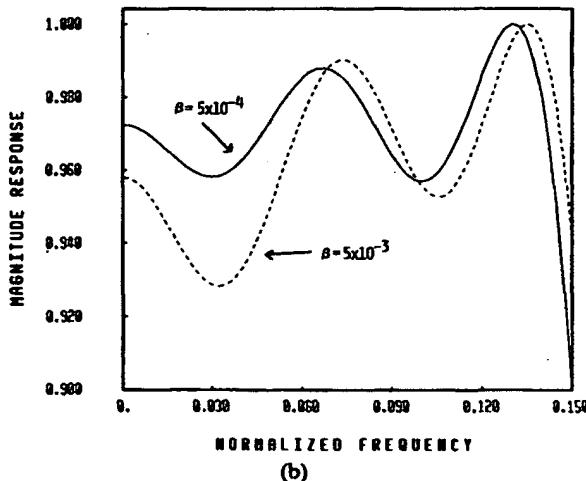

The overall quadratic objective function to be minimized is therefore

$$E = (1 - \alpha - \beta) E_p + \alpha E_S + \beta E_N \\ = b' [(1 - \alpha - \beta) P_p + \alpha P_S + \beta P_N] b \quad (39)$$

where $\alpha \geq 0$, $\beta \geq 0$, and $\alpha + \beta \leq 1$. Once again, for a given

Fig. 10. (Ex. 5) The appearance of the unwanted signal s_n .

(a)

(b)

Fig. 11. (Ex. 5) (a) Frequency response of an eigenfilter having simultaneous time-domain constraint. (b) Passband details.

set of parameters (ω_p , ω_s , α , and β), the filter design can be completed by finding the eigenvector of the matrix

$$P = (1 - \alpha - \beta)P_p + \alpha P_s + \beta P_N \quad (40)$$

corresponding to its minimum eigenvalue. Notice that $P = P^T > 0$.

Example 5: As a numerical example, let $N - 1 = 28$, $L - 1 = 19$, $\omega_p = 0.3(\pi)$, $\omega_s = 0.4(\pi)$, and $\alpha = 0.5$, and let the waveform s_n be as in Fig. 10. Fig. 11 shows the

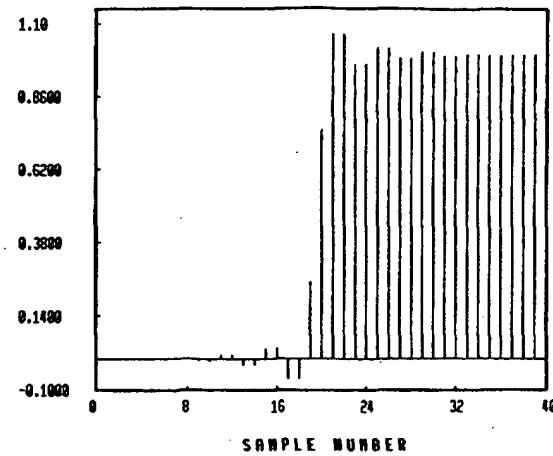

Fig. 12. A typical step response for a low-pass filter.

resulting frequency response of the linear-phase eigenfilter with $\beta = 5 \times 10^{-4}$ (solid lines) and with $\beta = 5.0 \times 10^{-3}$ (broken lines).

In an analogous manner, it is possible to put constraints on the unit step response. Notice that the first $k + 1$ coefficients of the step response t_n are given by

$$t = \begin{pmatrix} t_0 \\ t_1 \\ \vdots \\ t_k \end{pmatrix} = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 1 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & 0 \\ 1 & 1 & \cdots & 1 \end{pmatrix} \begin{pmatrix} h_0 \\ h_1 \\ \vdots \\ h_k \end{pmatrix} \quad (41)$$

It is often required to control (minimize) the energy in the step response over the interval $0 \leq n \leq k$, where k is the time taken for the beginning of a monotone rise (Fig. 12). Once again, the energy $t^T t$ can be written in the form $b^T P_T b$, where $P_T = P_T^T > 0$. Thus, additional quadratic constraints can be introduced into the problem in this manner before computing the eigenfilter.

IV. EQUIRIPPLE LINEAR-PHASE EIGENFILTERS

There exists a powerful technique [1] based on a Remez exchange procedure for designing equiripple filters by minimizing the L_∞ norm of the response error. In view of the availability of such excellent techniques, the question arises as to why we should manipulate an eigenfilter to give an equiripple response. The answer lies in the fact that eigenfilters can be designed so as to take into account other design constraints such as time-domain constraints, as illustrated in Section III. In addition, eigenfilters can be used for designing Nyquist filters by elegant modifications of the positive-definite matrices appearing in the objective function (Section V). For such applications, if we have a technique for equalizing the error over each band, the result is of a more or less equiripple nature, and the peak error tends to get minimized. With this motivation, we describe the algorithm for accomplishing this as follows.

The quantities E_p and E_s in (18) and (14) are the error measures in the frequency domain. Suppose we incorporate a positive-valued weighting function $W(\omega)$ into the integrands

$$E_s = \frac{1}{\pi} \int_{\omega_s}^{\pi} e_s^2(\omega) W(\omega) d\omega \quad (42)$$

and

$$E_p = \frac{1}{\pi} \int_0^{\omega_p} e_p^2(\omega) W(\omega) d\omega \quad (43)$$

where

$$e_S(\omega) = b'c \quad e_p(\omega) = (1 - c)'b. \quad (44)$$

For uniform weighting (i.e., with $W(\omega) \equiv 1$), the errors $e_p(\omega)$ and $e_S(\omega)$ of the resulting eigenfilter are large near the band edges and tend to fall off at points away from the band edges (see Fig. 4, Example 2). Accordingly, if $W(\omega)$ is larger near the band edges than at other points, the error tends to get equalized. Since the exact shape of the eigenfilter's error responses $e_p(\omega)$, $e_S(\omega)$ is not known *a priori*, we follow an iterative procedure to identify the appropriate $W(\omega)$ as follows.

Let $e_{p,k}(\omega)$ and $e_{S,k}(\omega)$ be the error curves for the eigenfilter at the end of the k th iteration. Then the weighting function for the $(k+1)$ th iteration is taken to be

$$W_{k+1}(\omega) = \begin{cases} W_k(\omega) \cdot |e_{p,k}(\omega)|, & 0 \leq \omega \leq \omega_p \\ W_k(\omega) \cdot |e_{S,k}(\omega)|, & \omega_S \leq \omega \leq \pi \end{cases} \quad (45)$$

Notice that either the errors $e_{p,k}(\omega)$ and $e_{S,k}(\omega)$ or their envelopes (which are monotone) can be used in (45). Once the errors become equiripple, the weighting function does not alter any more with further iterations, and we can stop the iteration. Note that, once we employ such weighting functions in (42) and (43), the integration should be performed numerically, thus increasing the design time.⁴ Another possible scheme for finding $W_{k+1}(\omega)$ would be to replace $e_{p,k}(\omega)$, $e_{S,k}(\omega)$ in (45) with a low-order polynomial that fits the envelope of the error. This would avoid the need for numerical integration, but should be weighed against the time required to obtain the polynomial fit.

Example 6: The eigenfilter considered in Example 2 was redesigned using the above procedure. The resulting design after 16 iterations has frequency response as shown in Fig. 13 (solid lines). The figure also shows the response of an optimal filter designed using the Remez exchange algorithm [1] (broken lines) with the same ω_p , ω_S and the same order $N-1$ as the eigenfilter. Notice that, for the equiripple eigenfilter, $\delta_p = 0.032$ and $\delta_S = -31.25$ dB, whereas, for the Remez-exchange-based optimal filter, $\delta_p = 0.031$ and $\delta_S = -31.2$ dB. Indeed, the tolerances achieved by the eigenfilter are very close to optimal. The numerical integration involved in the updating equation (45) was performed by using Simpson's rule, with 100 grid points. As a rule of thumb, the number of grid points can be taken to be about 20 to 30 times the approximate number of extrema in the frequency band under consideration. We are not aware of a proof that the above technique for equiripple designs always converges to the optimal solution. However, all of our design examples demonstrate such convergence.

⁴We learned from a reviewer that this kind of error feedback technique is in fact known [27], [28].

V. DESIGN OF NYQUIST EIGENFILTERS

The design of digital Nyquist filters for generating a band-limited pulse for data transmission with minimum intersymbol interference has a significant role in the design of digital modem systems [12]–[15]. The impulse response of a Nyquist filter of length N satisfies

$$h_n = 0 \quad \text{for } \left(n - \frac{N-1}{2} \right) = \text{nonzero multiple of } K.$$

These have also been known as K th-band filters [8]. Such filters are also of great interest in the design of interpolation filters [31, ch. 4] in multirate signal processing. The cutoff frequencies ω_p and ω_S of a Nyquist filter satisfy the condition $\omega_p + \omega_S = 2\pi/K$, where K is the intersymbol duration.

The design of Nyquist filters requires an algorithm that incorporates both time-domain and frequency-domain constraints. Such designs using linear programming or based on the Remez exchange algorithm have recently been suggested by several authors [8], [9], [15]. In this section, we would like to apply the eigenfilter approach, with some additional modifications on the objective function, to design the Nyquist filter. Recall from Section II

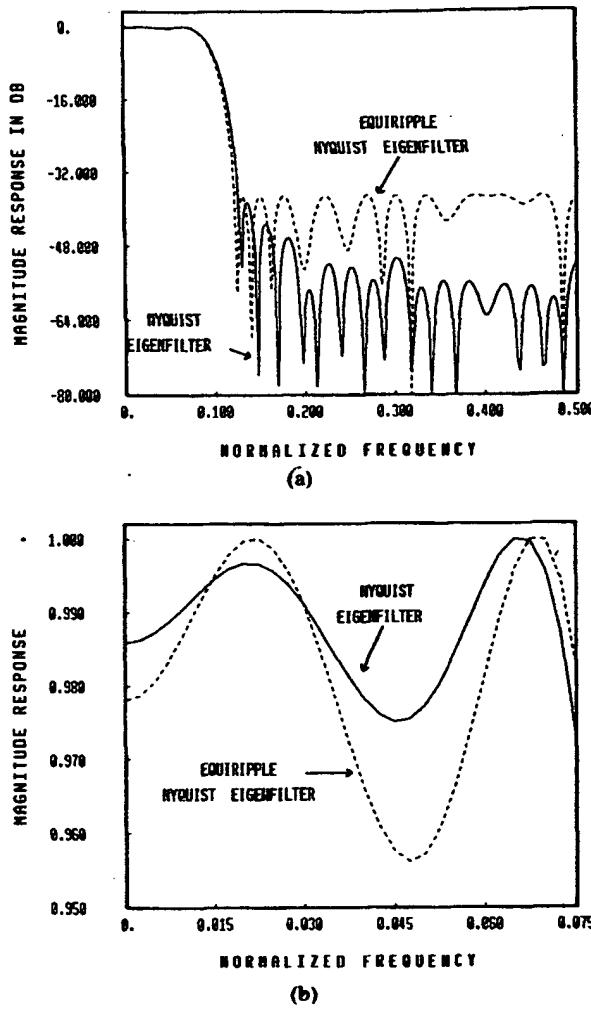

Fig. 14. (Ex. 7) (a) Nyquist eigenfilter response. (b) Passband details.

that the error E is given by (21) for a low-pass design, where P is as in (22). We note that every K th coefficient except the mid-term of the impulse response of a Nyquist filter is exactly zero; hence

$$\mathbf{b}' = [b_0, b_1, \dots, b_{K-1}, 0, b_{K+1}, \dots, b_{2K-1}, 0, b_{2K+1}, \dots]. \quad (46)$$

Therefore, those rows and columns of P whose indices are multiples of K do not contribute to the total error $E = \mathbf{b}'P\mathbf{b}$. To take advantage of this fact, we restate our problem as minimizing the error $E_1 = \mathbf{b}'P'\mathbf{b}'$, where

$$\mathbf{b}' = [b_0, b_1, \dots, b_{K-1}, b_{K+1}, \dots, b_{2K-1}, b_{2K+1}, \dots] \quad (47)$$

and

$$P' = \begin{pmatrix} P_{0,0} & \cdots & P_{0,K-1} & P_{0,K+1} & \cdots & P_{0,2K-1} & P_{0,2K+1} & \cdots \\ P_{1,0} & \cdots & P_{1,K-1} & P_{1,K+1} & \cdots & P_{1,2K-1} & P_{1,2K+1} & \cdots \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots \\ P_{K-1,0} & \cdots & P_{K-1,K-1} & P_{K-1,K+1} & \cdots & P_{K-1,2K-1} & P_{K-1,2K+1} & \cdots \\ P_{K+1,0} & \cdots & P_{K+1,K-1} & P_{K+1,K+1} & \cdots & P_{K+1,2K-1} & P_{K+1,2K+1} & \cdots \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots \\ P_{2K-1,0} & \cdots & P_{2K-1,K-1} & P_{2K-1,K+1} & \cdots & P_{2K-1,2K-1} & P_{2K-1,2K+1} & \cdots \\ P_{2K+1,0} & \cdots & P_{2K+1,K-1} & P_{2K+1,K+1} & \cdots & P_{2K+1,2K-1} & P_{2K+1,2K+1} & \cdots \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots \end{pmatrix}. \quad (48)$$

Note that the order of P' is smaller than the order of P ; we, therefore, save time in the design process. Once we find the appropriate eigenvector of P' , we insert the zeros that are required in the Nyquist filter impulse response. This completes the design. Once again, we can feedback the error in both passband and stopband of the previous iteration to compute P and P' according to (42) and (43) of Section IV to obtain an approximately equiripple frequency response for the Nyquist filter. (In such examples where we have both time- and frequency-domain specifications, it is, in general, not possible to get an exactly equiripple solution.) Notice that the resulting filter automatically has linear phase because we are directly solving for the vector \mathbf{b} .

Example 7: A Nyquist filter with order $N-1 = 38$, $\omega_p = 0.15(\pi)$, $\omega_s = 0.25(\pi)$, $K = 5$, and $\alpha = 0.95$ is designed using the eigenfilter approach. The frequency response of the Nyquist filter (solid lines) as well as of the equiripple Nyquist eigenfilter (broken lines) obtained from the techniques described in Section IV are shown in Fig. 14. Note that the transition band of the equiripple Nyquist eigenfilter is smaller than that of the Nyquist eigenfilter, and explains why the peak errors are larger for the equiripple design.

Example 8: A FIR linear-phase Nyquist eigenfilter with length 39, $\omega_p = 0.2125(\pi)$, $\omega_s = 0.2875(\pi)$, $\alpha = 0.98$, and $K = 4$ is designed. This is compared to the Nyquist filter with the same specifications, designed by linear programming [9] and also the design based on the Remez exchange algorithm [8]. We summarize the passband error δ_p and stopband error δ_s for these approaches.

	Eigenfilter	Remez	Linear Programming
δ_p (db)	-0.45	-0.335	-0.45
δ_s (db)	-33.21	-29.7	-33

The plot of the frequency response using the eigenfilter (solid curve) and MP approaches [8] (broken lines) are shown in Fig. 15. The frequency-response plot of the Nyquist filter designed using linear programming can be found in [9]. Notice that the eigenfilter response is slightly better in the stopband than that of the Remez exchange method, and slightly worse in the passband. A readjustment of α in (22) can produce results much closer to the Remez exchange procedure.

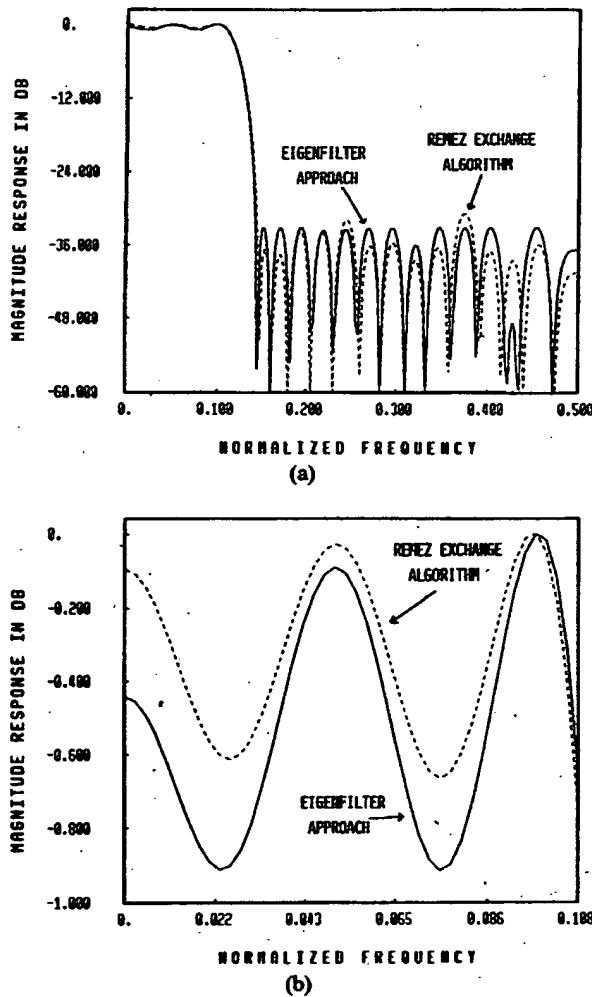

Fig. 15. (Ex. 8) (a) Magnitude response of Nyquist filter, designed using the eigenfilter approach and Remez exchange algorithm. (b) Passband details.

and

$$\mathbf{v} = \left[1 \quad \sin^2\left(\frac{\omega}{2}\right) \quad \sin^4\left(\frac{\omega}{2}\right) \quad \dots \quad \sin^{2(M-1)}\left(\frac{\omega}{2}\right) \quad \sin^{2M}\left(\frac{\omega}{2}\right) \right]^T \quad (53)$$

we then have

$$H_0(e^{j\omega}) = \mathbf{d}' \mathbf{v}. \quad (54)$$

To achieve a $2L+1$ degree of flatness at $\omega = 0$, we define new sequences \mathbf{d}' and \mathbf{v}' as

$$\mathbf{d}' = [d_0 \quad d_{L+1} \quad d_{L+2} \dots d_{M-1} \quad d_M]^T \quad (55)$$

$$\mathbf{v}' = \left[1 \quad \sin^{2(L+1)}\left(\frac{\omega}{2}\right) \quad \sin^{2(L+2)}\left(\frac{\omega}{2}\right) \quad \dots \quad \sin^{2(M-1)}\left(\frac{\omega}{2}\right) \quad \sin^{2M}\left(\frac{\omega}{2}\right) \right]^T. \quad (56)$$

VI. EIGENFILTERS THAT HAVE ARBITRARY DEGREE OF FLATNESS AT ANY GIVEN FREQUENCY IN THE PASSBAND

Digital FIR filters with a maximally flat frequency response at frequency $\omega = 0$ have been studied by Herrmann [21], Kaiser [22], and Vaidyanathan [23]. FIR filters of this class find applications in several filtering problems, as pointed out by Kaiser and Steiglitz [24]. In

this section, we impose the flatness constraints at any frequency in the passband using the eigenfilter approach.

Consider an even-order filter (type 1) $H(z)$ of order $N-1$. Its amplitude response can be written as a function of $\sin^2(\omega/2)$, i.e.,

$$\begin{aligned} H_0(e^{j\omega}) &= \sum_{n=0}^M b_n \cos n\omega = \sum_{n=0}^M c_n \cos^2 n\left(\frac{\omega}{2}\right) \\ &= \sum_{n=0}^M d_n \sin^2 n\left(\frac{\omega}{2}\right). \end{aligned} \quad (49)$$

Suppose the first $L+1$ coefficients (except d_0) of $H_0(e^{j\omega})$ are zero, i.e.,

$$\begin{aligned} H_0(e^{j\omega}) &= d_0 + d_{L+1} \sin^{2(L+1)}\left(\frac{\omega}{2}\right) \\ &\quad + d_{L+2} \sin^{2(L+2)}\left(\frac{\omega}{2}\right) + \dots + d_M \sin^{2M}\left(\frac{\omega}{2}\right). \end{aligned} \quad (50)$$

Clearly, the first $2L+1$ derivatives of $H_0(e^{j\omega})$ are zero at $\omega = 0$, i.e.,

$$\frac{d^{(k)}}{d\omega^k} H_0(e^{j\omega}) = 0, \quad 1 \leq k \leq 2L+1. \quad (51)$$

This fact suggests a procedure to design filters with flatness constraints using the eigenfilter approach. Defining

$$\mathbf{d} = [d_0 \quad d_1 \quad d_2 \dots d_{M-1} \quad d_M]^T \quad N-1 \text{ even} \quad (52)$$

Incorporating this into (15) and (20), we have the new objective function $E = (\mathbf{d}')^T \mathbf{P} \mathbf{d}'$, where \mathbf{P} is as in (22) with

$$\mathbf{P}_S = \frac{1}{\pi} \int_{\omega_0}^{\pi} \mathbf{v}' \mathbf{v}'' d\omega \quad (57)$$

$$\mathbf{P}_P = \frac{1}{\pi} \int_0^{\pi} (\mathbf{1}' - \mathbf{v}') (\mathbf{1}' - \mathbf{v}'')^T d\omega \quad (58)$$

where $\mathbf{1}' = [1 \quad 0 \quad 0 \quad \dots \quad 0]^T$. Now if we find the eigen-

vector corresponding to the minimum eigenvalue of P , the resulting response has the desired flatness at $\omega = 0$. We can easily generalize this approach when the flatness constraints are required at an arbitrary frequency. Thus, the frequency ω_0 at which the first $2L+1$ derivatives are zero can be varied by expanding $H_0(e^{j\omega})$ in terms of $\sin^{2n}(\omega - \omega_0/2)$ in (49).

VII. EIGENVECTOR COMPUTATION AND RELATED ISSUES

A major part of the design time for our method is spent in the computation of the eigenvector. Since we are interested in only one eigenvector (corresponding to an extremal eigenvalue), this computation can be done efficiently (without invoking general methods such as the QR technique [29]). It is well known [25], [26] that to compute the dominant eigenvalue and its corresponding eigenvector, the iterative power method is simple and fast if the ratio $|\lambda_N/\lambda_{N-1}|$ is large where λ_k are the eigenvalues of P with

$$|\lambda_N| \geq |\lambda_{N-1}| \geq \dots \geq |\lambda_2| \geq |\lambda_1|.$$

At the $k+1$ th iteration of the power method, a vector x_{k+1} is computed from the previous iterate x_k as

$$y_{k+1} = Px_k \quad (59a)$$

$$x_{k+1} = y_{k+1} / \|y_{k+1}\| \quad (59b)$$

where $\|\mathbf{v}\|$ denotes the L_2 norm of vector \mathbf{v} . The difference between x_k and x_{k+1} , defined by $\|x_{k+1} - x_k\|$ is compared to a prescribed small constant ϵ , and if

$$\|x_{k+1} - x_k\| \leq \epsilon \quad (60)$$

then x_{k+1} is a good approximation of the eigenvector corresponding to the maximum eigenvalue. A typical value for ϵ is about 1.0×10^{-6} .

We, however, wish to compute the *minimum* eigenvalue and its corresponding eigenvector. In other words, at each iteration, we would like to compute

$$x_{k+1} = P^{-1}x_k. \quad (61)$$

Given x_k , we would like to find x_{k+1} without inverting P^{-1} . Rewrite (61) as

$$x_k = Px_{k+1}. \quad (62)$$

It is well known [25], [26] that a real, symmetric, and positive-definite matrix P can be decomposed into

$$P = LL' \quad (63)$$

where L is a real lower triangle matrix. Equation (62) then becomes

$$x_k = LL'x_{k+1}. \quad (64)$$

Let

$$v_{k+1} = L'x_{k+1}. \quad (65)$$

Then

$$x_k = Lv_{k+1}. \quad (66)$$

We can find v_{k+1} in (66), given x_k and L , by recursively solving a set of linear equations. Let l_{ij} be the element in the i th row and j th column of L ; then we can show that

$$v_{k+1}(n) = \frac{1}{l_{nn}} \left\{ x_k(n) - \sum_{j=0}^{n-1} l_{nj} v_{k+1}(j) \right\}. \quad (67)$$

Since P is positive-definite, l_{nn} in (67) are evidently non-zero. Using (67), we first solve for $v_{k+1}(0)$ and solve recursively for all $v_{k+1}(n)$ for $1 \leq n \leq N-1$, where N is the dimension of L . (In (67), $x_k(n)$ denotes the n th element of vector x_k .) It takes $N(N-1)/2$ multiplications, N divisions, and $N(N-1)/2$ additions to compute v_{k+1} . Similarly, we can find x_{k+1} in (65) given v_{k+1} and L . The total time required per iteration is thus

$$\left[(t_a + t_m) \frac{N(N-1)}{2} + Nt_d \right] \times 2 = (t_a + t_m)N(N-1) + 2Nt_d$$

where t_a, t_m, t_d are, respectively, the required computer times for addition, multiplication, and division.

Note that the speed of convergence depends on the ratio λ_2/λ_1 since we are dealing with P^{-1} rather than P . Instead of proceeding as in (65) and (66), one could invert P beforehand, store it as Q , and then perform the iteration

$$y_{k+1} = Qx_k \quad (68a)$$

$$x_{k+1} = y_{k+1} / \|y_{k+1}\|. \quad (68b)$$

The operation (68a) requires N^2 multiplications and $N(N-1)$ additions, and the time required for this is

$$t_a N(N-1) + t_m N^2$$

which is nearly the same as the time required for performing (65) and (66). However, there is an overhead cost associated with the computation of Q .

Example 9: Table I indicates a comparison of design time for half-band filters, using the eigenfilter approach and the Remez exchange approach, for various tolerances. The ratio λ_2/λ_1 and the number of iterations required for eigenvector computation are also given. We observe that λ_2/λ_1 is large and, hence, the number of iterations for eigenvector computation is impressively small for all the entries in Table I.

We also summarize below the design time, number of iterations, λ_2/λ_1 , δ_1 , and δ_2 for the Nyquist filter designed in *Example 8* (solid curve in Fig. 15):

CPU time (sec)	Number of iterations	λ_2/λ_1	δ_1 (db)	δ_2 (db)
3.9	3	792	-0.45	-33

Our experience based on a large number of design examples has convinced us that the ratio λ_2/λ_1 is large in all practical cases. Accordingly, the eigenvector computation never creates any numerical or stability problems and is invariably fast. Single precision arithmetic is found to be sufficient in all design examples.

TABLE I

$n-1$ is the required order for peak passband ripple δ_1 and transition band-width $2(\pi/2 - \alpha_p)$.

There exist some recent methods for computing eigenvectors (corresponding to extremal eigenvalues) based on gradient techniques [30]. These could prove to be even faster than the iterative power method, but we have not studied this possibility in the context of our paper.

VIII. CONCLUDING REMARKS

In this paper, we have formulated linear-phase FIR design problems in the form of eigenproblems. The filter coefficients are computed from eigenvectors of certain matrices which represent the specification requirements. A set of specification requirements directly leads to the Kaiser-window frequency response. Eigenfilters can be designed in such a way that various time-domain requirements are simultaneously taken into account. By means of an error-feedback mechanism, an iterative method also has been presented that leads to near-equiripple eigenfilters. The eigenfilter approach is also used to design Nyquist filters and filters with flatness constraints in the frequency domain. In conclusion, a wide variety of specifications can be taken into account by the eigenfilter approach. The design examples presented and the design times compare favorably with several other methods reported in the literature.

ACKNOWLEDGMENT

The authors are grateful to the reviewers for useful comments and suggestions. Also, valuable discussions with Quan Phuong Hoang, graduate student at Caltech, on computational aspects are gratefully acknowledged.

Electrical Engineering. His main research interests are in digital signal processing, linear systems, and filter design.

Dr. Vaidyanathan served as the Vice-Chairman of the Technical Program Committee for the 1983 IEEE International Symposium on Circuits and Systems. He currently serves as an Associate Editor for the *IEEE TRANSACTIONS ON CIRCUITS AND SYSTEMS*. He was the recipient of the Award for Excellence in Teaching at the California Institute of Technology for 1983/84. He was also a recipient of the NSF's Presidential Young Investigator Award, starting from the year 1986.

P. P. Vaidyanathan (S'80-M'83) was born in Calcutta, India, on October 16, 1954. He received the B.Sc. (with honors) degree in physics, and the B. Tech. and M. Tech. degrees in radio-physics and electronics from the University of Calcutta, India, in 1974, 1977, and 1979, respectively, and the Ph.D. degree in electrical and computer engineering from the University of California, Santa Barbara, in 1982.

He was a Postdoctoral Fellow at the University of California, Santa Barbara, from September 1982 to February 1983. Since March 1983, he has been with the California Institute of Technology, Pasadena, as an Assistant Professor of

Truong Q. Nguyen (S'85) was born in Saigon, Vietnam, on November 2, 1962. He received the B.S. (with honors) and M.S. degrees from the California Institute of Technology in electrical engineering in 1984 and 1985, respectively, and is currently pursuing the Ph.D. degree at the same institution. He is a recipient of a fellowship from Aerojet General for advanced studies. Mr. Nguyen's main research interests are in digital signal processing and filter designs. He is a member of Tau Beta Pi and Eta Kappa Nu.
